

Virtual Knots and Links

Louis H. Kauffman
and
Vassily O. Manturov

Abstract

This paper is an introduction to the subject of virtual knot theory, combined with a discussion of some specific new theorems about virtual knots. The new results are as follows: We prove, using a 3-dimensional topology approach that if a connected sum of two virtual knots K_1 and K_2 is trivial, then so are both K_1 and K_2 . We establish an algorithm, using Haken-Matveev technique, for recognizing virtual links. This paper may be read as both an introduction and as a research paper.

For more about Haken-Matveev theory and its application to classical knot theory, see [Ha, Hem, Mat, HL].

1 Introduction

Virtual knot theory was proposed by Louis Kauffman in 1996, see [KaV]. The combinatorial notion of virtual knot ¹ is defined as an equivalence class of 4-valent plane diagrams (4-regular plane graphs with extra structure) where a new type of crossing (called virtual) is allowed.

This theory can be regarded as a “projection” of the knot theory in thickened surfaces $S_g \times \mathbf{R}$ (for example, as studied in [JKS]). Regarded from this point of view, virtual crossings appear as artifacts of the diagram projection from S_g to $\mathbf{R}^2$. In such a virtual projection diagram, one does not know the genus of the surface from which the projection was made, and one wants to have intrinsic rules for handling the diagrams. The rules for handling the virtual diagrams can be motivated (in [KaV]) by the idea of a knot diagram to its oriented Gauss code. A Gauss code for a knot is list of crossings encountered on traversing the knot diagram, with the signs of the crossings indicated, and whether they are over or under in the course of the traverse. Each crossing is encountered twice in such a traverse, and thus the Gauss code has each crossing label appearing twice in the list. One can define Reidemeister moves on the Gauss codes, and thus abstract the knot theory from its planar diagrams to a theory of all oriented Gauss codes, including those that do not have embedded realizations in the plane. Such non-planar Gauss codes are then described by planar

¹In the sequel, we use the generic term “knot” for both knots and links, unless otherwise specified

diagrams with extra “virtual” crossings, or by knots in thickened surfaces of higher genus. Virtual knot theory is the theory of such Gauss codes, not necessarily realizable in the plane. When one takes such a non-realizable code, and attempts to draw a planar diagram, virtual crossings are needed to complete the connections in the plane. These crossings are artifacts of the planar projection. It turns out that these rules describe embeddings of knots and links in thickened surfaces, stabilized by the addition and subtraction of empty handles (i.e. the addition and subtraction of thickened 1-handles from the surface that do not have any part of the knot or link embedded in them) [KaV2, KaV4, Ma1, Ma8, Ma10, CKS, KUP].

Another approach to Gauss codes for knots and links is the use of Gauss diagrams as in [GPV]). In this paper by Goussarov, Polyak and Viro, the virtual knot theory, taken as all Gauss diagrams up to Reidemeister moves, was used to analyze the structure of Vassiliev invariants for classical and virtual knots. In both [KaV] and [GPV] it is proved that if two classical knots are equivalent in the virtual category [KUP], then they are equivalent in the classical category. Thus classical knot theory is properly embedded in virtual knot theory.

To date, many invariants of classical knots have been generalized for the virtual case, see [GPV, KaV, KR, Ma1, Ma2, Ma8, Ma10, Saw, SW]. In many cases, a classical invariant extends to an invariant of virtual knots. In some cases one has an invariant of virtuals that is an extension of ideas from classical knot theory that vanishes or is otherwise trivial for classical knots. See [Saw],[SW], [KR], [Ma2, Ma3, Ma5]. Such invariants are valuable for the study of virtual knots, since they promise the possibility of distinguishing classical from virtual knots in key cases. On the other hand, some invariants evaluated on classical knots coincide with well known classical knot invariants (see [KaV, KaV2, KaV4, Ma3] on generalizations of the Jones polynomial, fundamental group, quandle and quantum link invariants). These invariants exhibit interesting phenomena on virtual knots and links: for instance, there exists a virtual knot K with “fundamental group” isomorphic to $\mathbf{Z}$ and Jones polynomial not equal to 1. This phenomenon immediately implies that the knot K is not classical, and underlines the difficulty of extracting the Jones polynomial from the fundamental group in the classical case.

We know in principle that the fundamental group, plus peripheral information, determines the knot itself in the classical case. It is not known how to extract the Jones polynomial from this algebraic information. The formally defined fundamental group of a virtual knot can be interpreted as the fundamental group of the complement of the virtual knot in the one-point suspension of a thickened surface where this knot is presented.

Another phenomenon that does not appear in the classical case are long knots [Ma11]: if we break a virtual knot diagram at two different points and take them to the infinity, we may obtain two different long knots.

Figure 1: Virtual crossing

In the present paper, we are going to discuss both algebraic and geometric properties of virtual knots. We recommend as survey papers for virtual knot theory the following [KaV2, Ma1, KUP, KaV4, KaV, FKM, FJK].

The paper is organized as follows. First, we give definitions and recall some known results. In the second section, we prove, using a 3-dimensional topology approach that if a connected sum of two virtual knots K_1 and K_2 is trivial, then so are both K_1 and K_2 . Here we say “a connected sum” because the connected sum is generally not well defined. In the third section we introduce Haken-Matveev theory of normal surfaces in order to establish an algorithm for recognizing virtual knots. The fourth section is devoted to self-linking coefficient that generalizes the writhe of a classical knot. The fifth section gives a quick survey of the relationship between virtual knots, welded knots and embeddings of tori in four-dimensional space.

We do not touch many different subjects on virtual knots. For instance, we do not describe virtual links and their invariants. For more details see [Kam, Ver, FRR, Ma14, Ma12, KL2].

1.1 Basic definitions

Let us start with the definitions and introduce the notation.

Definition 1. A virtual link diagram is a planar graph of valency four endowed with the following structure: each vertex either has an overcrossing and undercrossing or is marked by a virtual crossing, (such a crossing is shown in Fig. 1).

All crossings except virtual ones are said to be *classical*.

Two diagrams of virtual links (or, simply, *virtual diagrams*) are said to be *equivalent* if there exists a sequence of *generalized Reidemeister moves*, transforming one diagram to the other one.

As in the classical case, all moves are thought to be performed inside a small domain; outside this domain the diagram does not change.

Definition 2. Here we give the list of generalized Reidemeister moves:

1. Classical Reidemeister moves related to classical vertices.
2. Virtual versions $\Omega'_1, \Omega'_2, \Omega'_3$ of Reidemeister moves, see Fig. 2.
3. The “semivirtual” version of the third Reidemeister move, see Fig. 3,

Figure 2: Moves $\Omega'_1, \Omega'_2, \Omega'_3$

Figure 3: The semivirtual move Ω''_3

Remark 1. The two moves shown in Fig. 4 are forbidden, i.e., they are not in the list of generalized moves and cannot be expressed via these moves.

Definition 3. A virtual link is an equivalence class of virtual diagrams modulo generalized Reidemeister moves.

One can easily calculate the number of components of a virtual link. A *virtual knot* is a one-component virtual link.

Exercise 1. Show that any virtual link having a diagram without classical crossings is equivalent to a classical unlink.

Remark 2. Formally, generalized Reidemeister moves appear to give a new equivalence relation for classical links: there seem to exist two isotopy relations for classical links, the classical one that we are used to work with and the virtual one. In [GPV], it is shown that, for classical knots and links, virtual and classical equivalences are the same.

Figure 4: The forbidden moves

Remark 3. *Actually, the forbidden move is a very strong one. Each virtual knot can be transformed to any other one by using all generalized Reidemeister moves and the forbidden move.*

This was first proved in [GPV] (see also [Nel, Kan]). Therefore, any two virtual knots can be transformed to each other by a sequence of generalised Reidemeister moves and the forbidden moves.

If we allow only the forbidden move shown in the left part of Fig. 4, we obtain what are called welded knots, developed by Shin Satoh, [Satoh]. Some initial information on this theory can be found in [Kam], see also [FRR]. A quick survey of this theory is given in section 5 of the present paper.

Definition 4. *By a mirror image of a virtual link diagram we mean a diagram obtained from the initial one by switching all types of **classical** crossings (all virtual crossings stay on the same positions).*

1.1.1 Projections from thickened surfaces

The choice of generalized Reidemeister moves is very natural. It is the complete list of moves that occur when considering a generic projection of $S_g \times I$ to $\mathbf{R}^2 \times I$ (or equivalently $\mathbf{R}^3$), i.e. thickened surface is projected generically to thickened plane. The virtual crossings appear in this projection as artifacts of different sheets of the surface being projected to the single sheet below. Actual crossings in the thickened surface are rendered as classical crossings in the thickened plane. The other moves, namely, the semivirtual move and purely virtual moves, are shown in Fig. 5 together with the corresponding moves in thickened surfaces.

Note that plane diagrams modulo classical Reidemeister moves lead to the classical knot theory as well as spherical diagrams (on S^2) modulo Reidemeister moves; in the sequel, we shall use spherical diagrams rather than planar ones.

In fact, there exists a topological interpretation for virtual knot theory in terms of embeddings of links in thickened surfaces [KaV, KaV2]. Regard each virtual crossing as a shorthand for a detour of one of the arcs in the crossing through a 1-handle that has been attached to the 2-sphere of the original diagram. The two choices for the 1-handle detour are homeomorphic to each other (as abstract manifolds with boundary). By interpreting each virtual crossing in such a way, we obtain an embedding of a collection of circles into a thickened surface $S_g \times \mathbf{R}$, where g is the number of virtual crossings in the original diagram L and S_g is the orientable 2-manifold homeomorphic to the sphere with g handles. Thus, to each virtual diagram L we obtain an embedding $s(L) \rightarrow S_{g(L)} \times \mathbf{R}$, where $g(L)$ is the number of virtual crossings of L and $s(L)$ is a disjoint union of circles. We say that two such surface embeddings are *stably equivalent* if one can be obtained from the other by isotopy in the thickened surface, homeomorphisms of surfaces, and the addition of subtraction or handles not incident to images of curves.

Theorem 1. *Two virtual link diagrams generate equivalent (isotopic) virtual links if and only if their corresponding surface embeddings are stably equivalent.*

Figure 5: Generalized Reidemeister moves and thickened surfaces

This result was sketched in [KaV]. The complete proof appears in [KaV3].

A hint to this proof is demonstrated in Fig. 5.

Here we wish to emphasize the following important circumstance.

Definition 5. A virtual link diagram is minimal if no handles can be removed after a sequence of Reidemeister moves.

An important Theorem by Kuperberg [KUP] says the following.

Theorem 2. For a virtual knot diagram K there exists a unique minimal surface in which an I -neighbourhood of an equivalent diagram embeds and the embedding type of the surface is unique up to isotopy of the image in the thickened surface.

Definition 6. The genus, $g(K)$, of a virtual knot or link is the genus of the unique minimal surface described in theorem 2.

1.1.2 Gauss diagram approach

Definition 7. A Gauss diagram of a (virtual) knot diagram K is an oriented circle (with a fixed point) where pre-images of overcrossing and

Figure 6: A virtual knot and its Gauss diagram

undercrossing of each **classical** crossing are connected by a chord. Pre-images of each crossing are connected by an arrow, directed from the pre-image of the overcrossing to the pre-image of the undercrossing. The sign of each arrow equals the local writhe number of the vertex (defined as in the classical case). Note that arrows (chords) correspond only to classical crossings.

Remark 4. For classical knots this definition coincides with the standard one.

Given a Gauss diagram with labelled arrows, if this diagram is realizable then it (uniquely) represents some classical knot diagram. Otherwise one cannot get any classical knot diagram.

Herewith, the four-valent graph represented by this Gauss diagram and not embeddable in $\mathbf{R}^2$ can be *immersed* to $\mathbf{R}^2$. Certainly, we shall consider only “good” immersions without triple points and tangencies.

Having such an immersion, let us associate virtual crossings with intersections of edge images, and classical crossings at images of crossings, see Fig. 6.

Thus, by a given Gauss diagram we have constructed (not uniquely) a virtual knot diagram.

Theorem 3 ([GPV]). The virtual knot isotopy class is uniquely defined by this Gauss diagram.

Remark 5. The equivalent result for Gauss codes is discussed in [KaV].

Exercise 2. Prove this fact.

Exercise 3. Show that purely virtual moves and the semivirtual move are exactly those moves that do not change the Gauss diagram at all.

2 Underlying genus of virtual knots

The connected sum for two classical knots is defined by breaking these diagrams at one point each and attaching one diagram to the other one respecting the orientation. This is a well-defined operation. Analogously, one can define a connected sum for virtual knots by means of their diagrams. It is well known that this operation is **not** well defined, see, e.g.,

Figure 7: A non-trivial connected sum of trivial virtual knots

[Ma12]: the definition of a connected sum depends on initial diagrams and the choice of break point.

Figure 7 illustrates a non-trivial connected sum of trivial virtual knots. This example is due to Kishino, [KS].

In what follows, we shall prove results for a connected sum $K_1 \# K_2$, with the intent that our statement holds *for any* connected sum: here the notation $K_1 \# K_2$ will be used for an arbitrary connected sum, unless otherwise specified.

The aim of this section is to prove the following.

Theorem 4. *Let K_1, K_2 be two virtual knots. Then $g(K_1 \# K_2) \geq g(K_1) + g(K_2) - 1$, whereas if $g(K_1) = 0$ or $g(K_2) = 0$ then $g(K_1 \# K_2) \geq g(K_1) + g(K_2)$. Here $g(K)$ is the genus defined at the end of the last section, the minimal genus in which K can be represented.*

From this theorem one can deduce the following

Theorem 5. *If K_1 and K_2 are virtual knots such that some connected sum $K_1 \# K_2$ is trivial, then both K_1 and K_2 are trivial knots.*

Indeed, if at least one of K_1, K_2 has positive underlying genus, then the underlying genus of their connected sum is also positive (by Theorem 4). In the case when both knots have underlying genus zero, one should mention the following.

Lemma 1. *If K_1 and K_2 are two classical knots then any connected sum $K_1 \# K_2$ of genus zero is equivalent to the (well-defined) classical connected sum $K_1 \# K_2$.*

This lemma follows directly from the proof of Theorem 4.

The remaining part of Theorem 5 now follows from the non-triviality of connected sum in the classical case. See [CF].

2.1 Two types of connected sums

Given two virtual knots K_1 and K_2 represented by knots in thickened surfaces, there are two natural possibilities to represent their connected sum as a knot in a thickened surface.

Remark 6. *In what follows, we shall use the same letter for an abstract virtual knot K and the knot lying in a thickened surface $M \times I$ and representing the knot K (abusing notation).*

We shall deal with 3-manifolds (possibly, with boundary) and 2-surfaces in these manifolds. A compact surface F in a manifold M is called *proper* if $F \cap \partial M = \partial F$. In the sequel, all surfaces are assumed to be proper.

Also, we assume that all surfaces considered in the manifold M intersect the knot transversally.

The first method for making the connected sum goes as follows. We take thickened surfaces $(M_1 \times I) \supset K_1$ and $(M_2 \times I) \supset K_2$ and cut two vertical full cylinders $D_i \times I$, where $D_i \subset M_i$, such that $(D_i \times I) \cap K_i$ is homeomorphic to an interval. Then we paste the obtained manifolds together (by identifying $\partial D_1 \times I$ and $\partial D_2 \times I$ with respect to the orientation of manifolds, the direction of the interval I and the orientation of knot at the two gluing points) and obtain $(M \times I) = ((M_1 \# M_2) \times I)$ with the knot $K_1 \# K_2$ inside.

Clearly, $g(M) = g(M_1) + g(M_2)$.

Another way to construct the connected sum works only in some special cases. Suppose K_1 and K_2 lie in $M_1 \times I, M_2 \times I$, where both $g(M_1)$ and $g(M_2)$ are greater than zero, and there exist two non-trivial (non zero-homotopic) curves $\gamma_1 \subset M_1$ and $\gamma_2 \subset M_2$ such that $(\gamma_i \times I) \cap K_i$ consists of precisely one point (note that in this case such a curve can not divide the 2-manifold into two parts). Then we cut the thickened surfaces $(M_i \times I)$ along $\gamma_i \times I$ and paste them together. Thus we obtain a manifold $M \times I$, where $g(M) = g(M_1) + g(M_2) - 1$ with some connected sum $K_1 \# K_2$ lying in M .

It turns out that these two connected sums are the only essential forms of connected summation for virtual knots, from which we deduce Theorem 5.

2.2 The proof plan of Theorem 5

Consider two virtual knots K_1 and K_2 and their connected sum $K_1 \# K_2$. Let us realize this connected sum by curves in thickened surfaces by using the first method. Denote the corresponding surfaces by $M_1, M_2, M_1 \# M_2$,

and denote the corresponding knots by $K_1, K_2, K_1 \# K_2$ (abusing notation). Now, we are going to transform $(M_1 \# M_2) \times I$ and knots inside it.

To simplify the notation, let us use the same letters for closed surfaces and surfaces with boundary. We will write $M = M_1 \# M_2$ and $M = M_1 \cup M_2$. We prefer the second notation to emphasize that both M_1 and M_2 are parts of M , while the first notation will be used when M_1 and M_2 are treated as separate manifolds.

We will perform a destabilization process on the knot obtained by the connected sum operation described in 2.1.

We are going to check that the following conditions hold during the destabilization process (all notation stays the same during the transformation):

1. The ambient manifold M can be divided into two parts $M_1 \# M_2$ such that $M_i \times I$ represents the knot K_i (i.e., if we close this manifold, we obtain a surface realization of K_i).
2. The intersection $M = M_1 \cap M_2$ consists of one or two components; so $(M_1 \times I) \cap (M_2 \times I)$ consists of one or two annuli.
3. The knot $K_1 \# K_2$ intersects the manifold $(M_1 \cap M_2)$ precisely at two points; in the case when $M_1 \cap M_2$ is not connected, these intersection points lie in different connected components.
4. The process stops when $g(M_1 \# M_2)$ is the minimal genus of the knot $K_1 \# K_2$.

If we organize the process as described above, we prove Theorem 5. Indeed, at each moment of the process we have K_1 and K_2 represented by knots in thickened surfaces of genera g_1 and g_2 . The knot $K_1 \# K_2$ lies in the surface of genus $g_1 + g_2$ if we deal with the connected sum of the first type and in the surface of genus $g_1 + g_2 - 1$ if we deal with the connected sum of the second type. So, the same holds when the process stops, thus we have $g(K_1 \# K_2) = g_1 + g_2$ or $g(K_1 \# K_2) = g_1 + g_2 - 1$, where the last case is possible only if we have the connected sum of the second type (hence, both g_1 and g_2 are greater than zero). Taking into account that g_i is the genus of a surface (not necessarily minimal) representing K_i , we obtain the statement of the theorem.

2.3 The process

In the present subsection we describe how this process works.

Suppose we have the connected sum of type i ($i = 1$ or 2) of the knots K_1 and K_2 . The main statement is the following.

Statement 1. *If there is a possibility to decrease the genus of $M_1 \# M_2$, then one of the following holds:*

1. *We can perform a destabilization in M_i without changing M_{3-i} and the connected sum type (thus, we decrease the genus of one of connected summands M_i by one, as well as that of $M_1 \# M_2$).*

2. If we have the first type connected sum, then there is a possibility to transform it to the connected sum of the second type, decreasing the genus of $M_1 \# M_2$ by one without changing the genera of M_1 and M_2 .
3. If we have the second type connected sum, then there is a possibility to transform it to the connected sum of the first type, decreasing each of $g(M_1), g(M_2), g(M_1 \# M_2)$ precisely by one.

Together with all points described above, this statement completes the proof of Theorem 5.

Proof of Statement 1. First, consider the case of the first type connected sum. We have $M = M_1 \# M_2$. Denote $M_1 \cap M_2$ by D . Suppose we are able to destabilize the pair $((M_1 \# M_2) \times I, K_1 \# K_2)$. Then there is a vertical annulus C in $M_1 \# M_2$ which does not intersect the knot $K_1 \# K_2$. If there is such an annulus which does not intersect D , then we can destabilize one of the summands along C ; this is the first case of Statement 1.

Suppose there is no such annulus C . Any C we consider will intersect D . Without loss of generality assume that the intersection between each such C and D is transverse. Let n be the minimal number of connected components of the intersection $C \cap D$.

Since C and D are manifolds with boundary (vertical annuli), their (generic) intersection may consist of:

1. simple circles;
2. trivial arcs;
3. horizontal circles;
4. vertical arcs;

Here the circle is *trivial* if it represents the trivial element in the fundamental group of the annulus C , otherwise the circle is called *horizontal*. The arc is called *trivial* if it connects points from the same boundary component of the annulus; otherwise it is called *vertical*.

If there is a trivial circle, then we can consider an innermost circle γ (with respect to C). This circle contains no intersection points with D inside. Because this disk together with a disk from D bounds a 3-ball, (see Fig. 8), we can slightly change the annulus C in such a way that the total intersection between C and D decreases, and C remains an annulus with non-contractible core. The same situation happens when we have a trivial arc, see Fig. 9.

Now, let us state two auxiliary lemmas.

Lemma 2. *Suppose S_g is the oriented surface of genus g and let Δ be an embedded disk in S_g . Then if a closed non self-intersecting curve $\gamma \in S_g \setminus \Delta$ is trivial in S_g and not trivial in $S_g \setminus \Delta$ then it is parallel to $\partial\Delta$ (i.e. $\gamma \cup \partial\Delta$ bounds a cylinder in S_g).*

Indeed, if a curve γ bounds a disk in S_g ; which does not intersect Δ then γ is contractible in $S_g \setminus \Delta$.

The following lemma is evident.

Figure 8: Non-horizontal disks in A_1

Figure 9: Removing the intersection along a non-vertical arc

Figure 10: The annulus C divided into sectors

Lemma 3. *If a proper annulus C' is free homotopic to the annulus D (rel boundary), then C' intersects the knot $K_1 \# K_2$.*

Now, we may assume that our intersection $C \cap D$ consists only of vertical arcs, or only of horizontal circles (the existence of a vertical arc contradicts the existence of a horizontal circle).

Suppose we have only horizontal circles. Then C is homotopic to D and, by Lemma 3, the annulus C intersects the knot $K_1 \# K_2$. Thus we obtain a contradiction.

Now, suppose the intersection $C \cap D$ consists only of vertical arcs. Then the annulus C is divided into $2k$ parts $C_1, \dots, C_{2k}$, whereas C_{2l+1} lies in $M_1 \times I$, and C_{2l} lies in $M_2 \times I$, where $l \in \{1, \dots, k\}$ when meaningful. The annulus $C \cap D$ is thus divided into $2k$ sectors by radii (more precisely, radial segments); some of these sectors contain intersection(s) with the knot, see Fig. 10. Denote all these radii by $r_1, \dots, r_{2k}$.

Now, each part C_i of the annulus C is incident to two radii r_j and r_k . Then D is divided into two parts by these radii. Denote these parts by D_{jk}^+ and D_{jk}^- . There are four options with respect to the following questions:

1. Is it true that any of the two parts D_{jk}^+ and D_{jk}^- intersect the knot precisely at one point?
2. Is it true that an annulus obtained by attaching C_i to one of D_{jk}^+ or D_{jk}^- , cuts off a ball (so that if we attach C_i to the other fragment, we get an annulus homotopic to D)?

Remark 7. *Here we mean that a proper surface (say, annulus) $F \subset M$ cuts a ball if $M \setminus F$ has two connected components, one of which is a*

Figure 11: Simplifying the curve C

topological ball. In other words, F bounds a ball together with a part P of boundary ∂M of the manifold M , so that $P \cup F$ is a 2-sphere.

First, consider the case when the answer to the first question is negative, i.e., one of the parts, say, D_{jk}^+ does not intersect the knot (whence the other part D_{jk}^- meets the knot twice).

If the annulus obtained by gluing C_i with D_{jk}^+ , cuts a ball then we may “pull” D_{jk}^+ through C_i ; this would decrease the number of intersection components between C and D . This leads to a contradiction.

If the annulus obtained by pasting C_i and D_{jk}^- cuts off a ball then the annulus $C_i \cup D_{jk}^+$ is homotopic to D ; thus it should intersect the knot. This leads to a contradiction again.

If both answers are affirmative, we get a contradiction: our knot can not meet the boundary of a ball precisely at one point.

Finally, if, say, D_{jk}^+ contains precisely one intersection point with the knot $K_1 \# K_2$ then the number of intersection components of $C \cap D$ should be equal to two.

Indeed, if it is greater than two, then it can be decreased as shown in Fig. 11. More precisely, among all parts C_i of the annulus C we take only two parts and compose a nontrivial annulus C' , along which $(M_1 \# M_2) \times I$ with the knot $K_1 \# K_2$ inside can be destabilized.

In other words, having more than two components C_i , one can find two of them which can be repasted and thus obtain a new non-trivial annulus C' intersecting D at a smaller number of curves and not intersecting the knot $K_1 \# K_2$.

Thus we see that if the intersection $C \cap D$ were minimal, there would be precisely two connected components.

Let us show that the destabilization along such C just transforms the type of connected sum: we obtain a connected sum of the second type.

Indeed, the disk D is just cut into two parts by this destabilization; and two intersection point after the destabilization lie in different connected components.

The proof for the case when we have the connected sum of the second type goes in the same vein. Either it is possible to destabilize only one of M_1 or M_2 or all annuli along which the stabilization can be performed intersect $M_1 \cap M_2$ (which consists of two components in this case). Considering such an annulus representing minimal intersection with $M_1 \cap M_2$, we get the only possibility when the destabilization transforms the connection type to the first type. $\square$

3 Algorithmic recognition of virtual links

The aim of this section is to prove the following

Theorem 6. *There is an algorithm to decide whether two virtual links are equivalent or not.*

This theorem was first proved in [Ma13], see also [Ma12].

We shall use the result by Moise [Moi] that each 3-manifold admits a triangulation. In the sequel, each 3-manifold is thought to be triangulated.

A manifold M is *irreducible* if each embedded sphere in M bounds a ball in M .

We shall use the definition of virtual knots as knots in thickened surfaces $\mathcal{M} \times I$ up to stabilizations/destabilizations. Here $\mathcal{M}$ is a compact 2-surface, not necessarily connected. Herewith we require that for each connected component $\mathcal{M}_i$, the 3-manifold $\mathcal{M}_i \times I$ contains at least one component of the link L .

Recall that a representative for a virtual link is *minimal* if it can not be destabilized.

We shall need Theorem 2 by Kuperberg [KUP].

Thus, in order to compare virtual links, we should be able to find their minimal representatives and compare them. The algorithm to be given below uses a recognition techniques for three-manifolds with boundary pattern (see definition below) connected to the virtual links in question.

We shall use the following facts from Haken-Matveev theory, see [Mat1].

A *compressing disk* for a surface F in a 3-manifold M is an embedded disk $D \subset M$ which meets F along the boundary of the disk, i.e. $D \cap F = \partial D$.

A surface (possibly disconnected) $F \subset M$ is called *compressible* in one of the two cases:

1. It admits a compressing disk D such that ∂D does not bound a disk in F ;
2. There is a ball in B such that $B \cap F = \partial B$.

A surface is *incompressible* if it is not compressible.

A surface $F \subset M$ is called *boundary compressible* if there exists a disk $D^2 \subset M$ such that $D^2 \cap (\partial M \cup F) = \partial D^2$ and $D^2 \cap F$ is a non-trivial arc in F (an arc that does not cut a disk from F).

Also, a 3-manifold M is *boundary irreducible* if for any proper disk $D \subset M$, ∂D bounds a disk on ∂M .

Given a 3-manifold with boundary. By a *boundary pattern* (first proposed by Johansson, see [Joh]) we mean a fixed 1-polyhedron (graph) without isolated points on the boundary of the three manifold (we assume this graph be a subpolyhedron of the selected triangulation).

The existence of a boundary pattern does not change the definition of incompressible surface and irreducible manifold.

We have straightforward generalizations of boundary incompressible surface and boundary irreducible manifold as described below. A disk $D \subset M$ is called *clean* if it does not intersect the pattern.

For boundary irreducibility we require that every clean proper disk cuts a ball (not intersecting the pattern). In the definition of boundary incompressible surface we require that every clean disk D^2 for which $D^2 \cap (\partial M \cup F) = \partial D^2$ and $l = \partial D^2 \cap F$ is an arc in F , the arc l cuts a clean disk from F .

Let F be a surface in a manifold (M, Γ) with boundary pattern.

Recall that an orientable 3-manifold M is *sufficiently large* if it contains a proper incompressible boundary incompressible surface distinct from S^2 and D^2 .

It is natural to consider the notion of sufficiently large manifold together with properties of irreducibility and boundary irreducibility. This leads to the following definition.

A connected 3-manifold without boundary (thus, without boundary pattern) is *Haken* if it is irreducible and sufficiently large. An irreducible boundary irreducible 3-manifold (M, Γ) with a boundary pattern Γ is Haken either if it is sufficiently large or if its pattern Γ is nonempty (hence, so is ∂M), and M is a handlebody but not a ball.

Definition 8. *Let M be an irreducible boundary irreducible 3-manifold. A proper annulus $A \subset M$ is called inessential if either it is parallel rel ∂ to an annulus in ∂M , or the core circle of A is contractible in M . Otherwise A is called essential.*

Any essential annulus in $S_g \times I$ with two boundary components lying in $S_g \times \{0\}$ and $S_g \times \{1\}$ is precisely an annulus along which we may destabilize.

A manifold with more than one connected component is called *Haken* if any connected component of it is Haken.

We shall use the following

Proposition 1 (Jaco-Rubinstein-Thompson, see, e.g., [Tho, Mat1]). *Any connected irreducible 3-manifold with nonempty boundary is either sufficiently large or a handle body.*

Later on, we deal with manifolds with non-empty boundary pattern. For this manifold to be Haken, it is sufficient to check that the manifold in question is irreducible and boundary irreducible but not a ball.

Lemma 4 (Jaco-Rubinstein-Thompson, see, e.g., [Tho, Mat1]). *There exists an algorithm to decide whether a manifold M is reducible; if it is so, the algorithm constructs a 2-sphere $S \subset M$ not bounding a ball in M .*

Lemma 5. [Mat1] *Classical links are algorithmically recognizable.*

This lemma follows from Haken's theory of normal surfaces; the proof is based on the following ideas: for each non-trivial non-split link, the complement in S^3 to the tubular neighborhood of this link is a Haken manifold. Endowing the boundary with a pattern, we will be able to restore the initial link. After that, the problem is reduced to the recognition problem for Haken manifolds, for details see [Mat1].

Lemma 6. [Mat1] *There is an algorithm to decide whether a Haken manifold M with a boundary pattern $\Gamma \subset \partial M$ has a proper clean essential annulus. If such an annulus exists, it can be constructed algorithmically.*

We shall use this lemma to define whether a given representative of a virtual link can be destabilized.

Lemma 7. [Mat1] *There is an algorithm to decide, whether two Haken manifolds (M, Γ) and (M', Γ') with boundary patterns are homeomorphic by means of a homeomorphism that maps Γ to Γ' .*

Consider an arbitrary representative of a virtual link L , i.e., a couple (M, L) , where $M = \tilde{M} \times I$ for some closed 2-surface $\tilde{M}$, and L is a link in M (we use the same letter L for denoting both the initial link and the representing link in M : abusing notation). Let N be a small open tubular neighborhood of the link L . Cut N from M . We obtain a manifold with boundary. Denote it by M_L . Its boundary consists of boundary components of M (two, if M is connected) and several tori; the number of tori equals the number of components of the link L . Let us endow each torus with a pattern Γ_L , representing the meridian of the corresponding component (we also add a vertex to make a graph from the meridional circle). Thus we obtain the manifold (M_L, Γ_L) with a boundary pattern.

It is obvious that the virtual link L (and the pair (M, L)) can be restored from (M_L, Γ_L) , since we know how to restore the manifold M by attaching full tori to the boundary components of M_L knowing meridians of these full tori.

Lemma 8. *Suppose a link L is not a split sum of a (nonempty) classical link and a virtual link. Then the manifold (M_L, Γ_L) with boundary pattern Γ_L is Haken.*

Proof. In virtue of Proposition 1, it remains to show that (any connected component) this manifold with boundary pattern is irreducible and boundary irreducible: by definition, it can not be a handlebody.

In the case when $g = 0$ we deal with classical links. Suppose $g > 0$. Then, for any connected orientable 2-surface S_g the manifold $S_g \times I$ is irreducible. Thus, if the link L is not classical (thus $g \neq 0$) then for its neighborhood $N(L)$, the set $(S_g \times I) \setminus N(L)$ might be reducible if and only if it contains a sphere S , bounding a ball in $S_g \times \{0, 1\}$ such that this ball contains some components of the link L . This means that

these components form a classical sublink of L separated from all other components.

Furthermore, since L is not a split sum of the unknot with some virtual link, the manifold M_L is boundary irreducible.

Indeed, each curve in $S_g \times \{0\}$ or in $S_g \times \{1\}$ which may bound a disk in $S_g \times I$ is contractible in the boundary. Thus, boundary reducibility can occur only if we have a proper disk with boundary lying on some torus — the boundary of the cut full torus. This should mean that the cut full torus corresponds to the split unknot of the link.

Thus, the considered manifold is irreducible and boundary irreducible and thus (by Proposition 1), Haken. $\square$

Now, let us prove the main theorem. Let L, L' be virtual links.

Step 1. Consider some representatives $(M, L), (M', L')$ of the virtual links in question. Let us construct the corresponding manifolds with boundary patterns. Denote them by $(M_L, \Gamma), (M'_{L'}, \Gamma')$.

Step 2. Define whether one of M_L or $M'_{L'}$ is reducible. If one of them is so, then, by Lemma 4, we may find a sphere not bounding a ball, and thus separate some classical components of the corresponding link.

Now, rename the manifolds with boundary patterns accordingly: i.e. we shall use the previous notation for what is left from manifolds by cutting off classical components.

Step 3. Define (by Lemma 6) whether it is possible to destabilize one of (M, L) or (M', L') . If it is possible, perform the destabilization. Return to Step 2.

Let us perform steps 2 and 3 while possible. Obviously, this process stops in a finite period of time.

Classical links are algorithmically recognizable. Thus, we may compare the split classical sublinks of L and L' . If they are not isotopic, we stop: the virtual links in question are not equivalent. Otherwise, we go on.

After performing the first three steps, we reduce our problem to the case when there are no split components and representatives are minimal. From now on, the manifolds in question are Haken by Lemma 8.

Step 4. Each connected component of the manifolds (M_L, Γ) and $(M'_{L'}, \Gamma')$ is a Haken manifold with a boundary pattern. Thus, we can algorithmically solve the problem whether there exists a homeomorphism $f : M_L \rightarrow M'_{L'}$ that maps Γ to Γ' (by Lemma 7). If such a homeomorphism exists then virtual links L, L' are equivalent. Otherwise L and L' are not equivalent.

Performing the steps described above, we solve the recognition problem. Theorem 6 is proved.

Remark 8. *The proof given above works also for oriented virtual links and framed virtual links.*

4 Self-linking Numbers for Virtual Links

Call a classical crossing in an oriented virtual knot diagram K *odd* if, in the Gauss code for that diagram there are an odd number of appearances of (classical) crossings between the first and the second appearance of i . Let

$$J(K) = w(K)|_{Odd(K)}$$

where $Odd(K)$ denotes the collection of odd crossings of K , and the restriction of the writhe to $Odd(K)$, $w(K)|_{Odd(K)}$, means the summation over the signs of the odd crossings in K . Then it is not hard to see that $J(K)$ is invariant of the virtual knot or link K . We call $J(K)$ the *self-linking number* of the virtual diagram K . This invariant is simple, but remarkably powerful.

If K is classical then $J(K) = 0$, since there are no odd crossings in a classical diagram.

Theorem 7. *Let K be a virtual knot and let K^* denote the mirror image of K (obtained by switching all the crossings of the diagram K). Then*

$$J(K^*) = -J(K).$$

Hence, if $J(K)$ is non-zero, then K is inequivalent to its mirror image. If K is a virtual knot and $J(K)$ is non-zero, then K is not equivalent to a classical knot.

We leave the proof of this Theorem and the proof of the invariance of $J(K)$ to the reader. See [SelfLink] for more about this invariant its generalizations.

View Figure 12. The two virtual knots in this figure illustrate the application of Theorem 7. In the case of the virtual trefoil K , the Gauss code of the shadow of K is $abab$; hence both crossings are odd, and we have $J(K) = 2$. This proves that K is non-trivial, non-classical and inequivalent to its mirror image. Similarly, the virtual knot E has shadow code $abcbac$ so that the crossings a and b are odd. Hence $J(E) = 2$ and E is also non-trivial, non-classical and chiral. Note that for E , the invariant is independent of the type of the even crossing c .

View Figure 13. The virtual knot K' in this figure has Gauss code $abcdcadb$, and $J(K') = 2$. Note that K' would be unknotted if we allowed the forbidden move (of other type). This example underlines why we forbid such moves in virtual knot theory.

5 Welded Braids and Tubes in Four-Space

The welded braid group WB_n can be interpreted as the fundamental group of the configuration space of n disjoint circles trivially embedded in three dimensional space $\mathbf{R}^3$. This group (the so-called motion group of disjoint

Figure 12: Virtual Trefoil K and Virtual Figure Eight E

Figure 13: The Knot K'

Figure 14: Tubular correspondence

circles) can, in turn, be interpreted as a braid group of tubes embedded in $\mathbf{R}^3 \times \mathbf{R} = \mathbf{R}^4$. These braided tubes in four-space are generated by two types of elementary braiding. In Figure 14, we show diagrams that can be interpreted as immersions of tubes in three-space. Each such immersion is a projection of a corresponding embedding in four-space. The first two diagrams of Figure 14 each illustrate a tube passing through another tube. When tube A passes through tube B we make a corresponding classical braiding crossing with arc A passing under arc B . The four-dimensional interpretation of tube A passing through tube B is that: As one looks at the levels of intersection with $\mathbf{R}^3 \times t$ for different values of t , one sees two circles $A(t)$ and $B(t)$. As the variable t increases, the $A(t)$ circle (always disjointly embedded from the $B(t)$ circle) moves through the $B(t)$ circle. This process is illustrated in Figure 15.

While the classical crossing in a welded braid diagram corresponds to a genuine braiding of the tubes in four-space (as described above), the virtual crossing corresponds to tubes that do not interact in the immersion representation (see again Figure 14). These non-interacting tubes can pass over or under each other, as these local projections correspond to equivalent embeddings in four-space.

It is an interesting exercise to verify that the moves in the welded braid group each induce equivalences of the corresponding tubular braids in four-space. In particular, the move (F_1) induces such an isotopy, while the forbidden move (F_2) does not. For more on this subject, the reader can consult [Satoh] and also [KaV2] and the references therein. The basic idea

Figure 15: Braiding of circles

for this correspondence is due to Satoh in [Satoh] where torus embeddings in four-space are associated with virtual knot diagrams.

For knot theory the moral of these remarks is that the category of welded knots and links (virtual knots and links plus the equivalence relation generated by the first forbidden move) is naturally associated with embeddings of tori in four dimensional space. To each welded knot or link there is associated a well-defined embedding of a collection of tori (one torus for each component of the given link) and the fundamental group of the complement of this embedding in four space is isomorphic to the combinatorial fundamental group of the welded link (this is the same as the combinatorial fundamental group of a corresponding virtual link). It is an open problem whether this association is an embedding of the category of welded links into the category of toroidal embeddings in four-space.
